

techniques which can be used to determine the unknown material properties. The characteristics that exhibit in the indentation load-displacement curve have a good relationship with the properties of the material such as Young's modulus, yield strength, strain hardening exponent, residual stress-strain, etc. [12] - [30].

Indentation hardness is determined by indenting a surface using a harder surface to form a permanent impression with plastic deformation. Based on the applied load and the penetration depth, indentation hardness can be categorized as macro, micro, and nano. Table 1 gives the ranges of applied loads ( $L$ ) and penetration depths ( $h$ ) specified by ISO 14577-1 norm for determining the above three categories [12].

**Table 1 - Hardness Testing Scales Defined by ISO 14577-1 [12]**

Scale	Load Range ( $L$ )/ ( $N$ )	Penetration Range ( $h$ )/ ( $\mu m$ )
Macro	$2 < L < 30,000$	Not-specified
Micro	$L < 2$	$h > 0.2$
Nano	Not-specified	$h < 0.2$

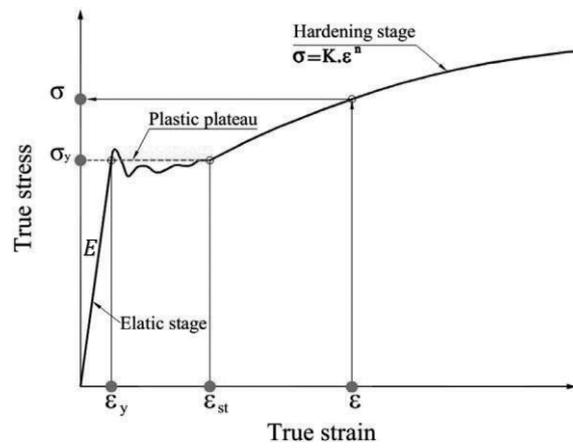

To determine the properties of the damaged structural members in structural health monitoring, macro-indentation is more suitable than others since micro and nano indentations are used to characterize the material properties of microscale and nanoscale objects such as bulk materials, thin films and coatings, integrated circuits (IC), etc. [13] - [16].

Brinell, Meyer, Rockwell, and Vickers are commonly used macro-indentation hardness tests. Based on the shape of the indenter, these macro-indentation tests can be divided into spherical indentation and sharp indentation. Spherical indentation loading-unloading curves contain more information on the material properties than those from a sharp indentation test [17]. In addition to that, spherical indentation has many advantages over a sharp indentation in the determination of material elastoplastic properties [13]. In the present work, we focus on the Brinell hardness test since it is the most used spherical indentation test type.

Spherical indentation has been used by many researchers to determine material elastic and plastic properties [13], [18] - [25]. However, most of them are valid only for the materials

without a plastic plateau in their true stress-strain behaviour [21] - [24]. The available methods for determining material properties of the materials with a plastic plateau in their true stress-strain behaviour such as, structural steel, are limited [25], [26].

Structural steels exhibit a plastic plateau in their true stress-strain curve. It is a plastic instability associated with the unpinning of dislocations from the interstitial elements in solid solution [27]. It initiates from the "upper yield stress" and ends at the beginning point of strain hardening ( $\epsilon_{st}$ ). Figure 1 illustrates the typical true stress-strain curve of structural steel.

**Figure 1 - Schematic Illustration of Typical True Stress-Strain Curve for Structural Steel**

The plastic plateau in the structural steel true stress-strain curve (solid curve between  $\epsilon_y$  and  $\epsilon_{st}$  in Figure 1) can be assumed as a perfectly plastic plateau (dotted line in Figure 1) to simplify the steel material model [26], [28]. Then, the stress-strain curve of structural steel can be expressed as Eq. (1) [26].

$$\sigma = \begin{cases} E\epsilon & ; \epsilon \leq \epsilon_y \\ \sigma_y & ; \epsilon_y \leq \epsilon \leq \epsilon_{st} \\ \sigma_y \left[ 1 + \frac{E(\epsilon - \epsilon_{st})}{\alpha\sigma_y} \right]^n & ; \epsilon > \epsilon_{st} \end{cases} \quad \dots(1)$$

where,

- $E$  = Young's modulus
- $\sigma_y$  = Initial yield stress
- $n$  = Strain hardening exponent
- $\alpha = \frac{\epsilon_{st}}{\epsilon_y}$

This study aims to analyse the sensitivity of indentation hardness to the structural steel material properties, Young's modulus ( $E$ ), yield strength ( $\sigma_y$ ), ratio ( $\alpha$ ) between the strain at beginning-point of strain hardening ( $\epsilon_{st}$ ) and

the yield strain ( $\epsilon_y$ ) and strain hardening exponent ( $n$ ). This sensitivity analysis will be helpful to develop a simple and cost-effective method based on hardness test to determine the unknown material properties of structural steel which can be easily used in the field. From that, the aforementioned problem can be addressed in the future.

Here, Brinell Hardness Number (BHN) is used to quantify the indentation hardness since BHN can be easily obtained from experimental Brinell hardness test within a short period of time. For a target metal specimen BHN can be found within acceptable limit from the numerical indentation simulations [29]. Therefore, the present study is fully based on a numerical approach. For a given material property, indentation load-displacement curves can be developed using finite element simulation. To model the indentation hardness test, two dimensional (2D) axisymmetric finite element simulation is used.

The summarized methodology is as follows. First, the Finite Element (FE) model is developed and validated using past experimental data [13]. Next, indentation load-displacement curves are obtained by varying the material properties,  $E$ ,  $\sigma_y$ ,  $\alpha$  and  $n$ . Here, to check the sensitivity of BHN to each material property, one material property is changed by fixing other material properties. Then, BHN is calculated for each material combination using indentation load-displacement curves and the variations of BHN with material properties are plotted. Finally, the sensitivity of BHN to each material property is calculated. Thereby, a comparison for the sensitivity of BHN to the material properties is made.

## 2. Finite Element Modelling of Macro-Indentation Simulation

The spherical indentation simulation is done using commercial nonlinear finite element (FE) analysis software package *ABAQUS* to obtain the load-displacement curves of macro-indentation for different material combinations. For the simulation of the hardness test, mainly two types of FE models can be used as 2D axisymmetric and 3D solid models. In this study, a 2D axisymmetric FE model is used to simulate the spherical indentation procedure with proper boundary conditions, considering the symmetries of both the geometry and the loading condition; see Figure 2 for the developed 2D ball indentation FE model.

In this indentation simulation, reduced integration and hourglass control elements are used with the application of the Von-Mises plasticity model and the contact theory. Since the hardness of the indenter is very high compared to the specimens, a rigid ball indenter is employed for indentation simulation and a rigid movable analytical surface is used to model the indenter. In addition to that, the computational time can be reduced by using a rigid indenter instead of a deformable indenter, because a 2D rigid indenter has three degrees of freedom at the reference point to control its behaviour [31].

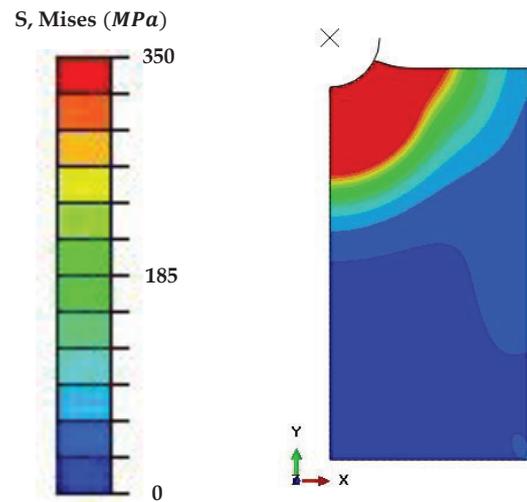

Figure 2 - 2D Ball indentation

The true stress-strain curves of different combinations of material properties are employed for the FE simulation. The specimen size should be selected such that boundary condition effects can be neglected. For that, sensitivity simulations were carried out by varying specimen diameter and depth for 1mm indentation depth and specimen size was selected as 20mm diameter, 20mm depth cylindrical specimen. The element type used for the specimen is 'CAX4R'. The meshes on the specimen are created such that they are finer near the indentation area and are coarser in the other parts of the specimen as shown in Figure 3.

The static general step is used with a time period of one second for each loading and unloading step. The penalty tangential behaviour is used as the interaction property between the indenter and the specimen with a 0.1 friction coefficient [25]. Then, a surface-to-surface contact interaction is created between them such that the outer surface of the indenter acts as a master surface and the top surface of

the specimen acts as a slave surface. Though the value of Poisson's ratio does not affect the indentation load-displacement curve, it is taken as 0.3 [30] for all material combinations.

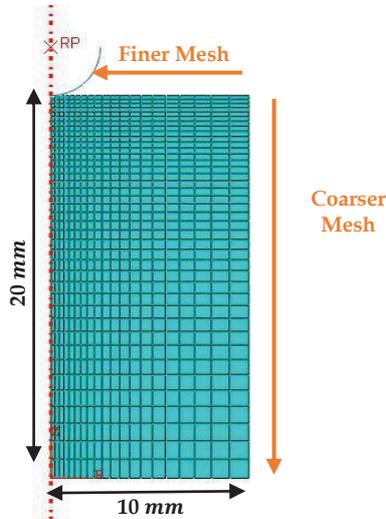

Figure 3 - Finite Element Mesh

The boundary conditions are applied such that a displacement-controlled indentation by allowing the rigid indenter to move along the  $y$  axis and penetrated up to the maximum depth into the specimen. The nodes on the  $y$  axis move only along the axis itself and the bottom of the specimen is fixed. See Figure 4 for the basic geometry and assembly of the 2D FE model with applied boundary conditions.

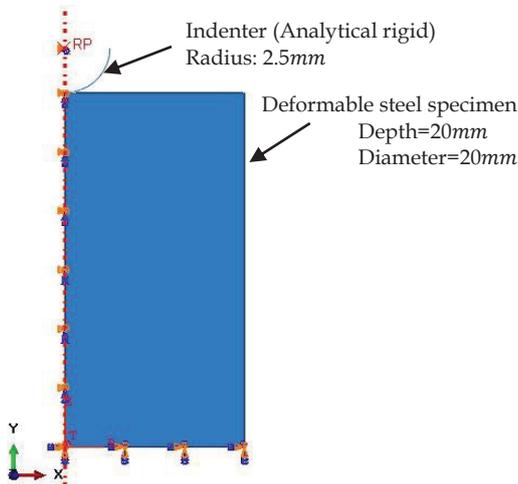

Figure 4 - Basic Geometry and Assembly of the 2D FE Model in ABAQUS

### 3. Validation of FE Model with Past Test Results

The validation of the ABAQUS FE model is done by using past experimental data of a ball indentation. A533-B steel with Young's modulus ( $E$ ) 210 GPa, yield strength ( $\sigma_y$ ) 400

MPa and strain hardening exponent ( $n$ ) 0.127 with 0.788 mm radius rigid ball indenter is used for the validation. The maximum penetration depth is taken as  $0.287mm \times R$  [13].

The comparison between the developed load-displacement curve for 2D ball indentation and that from the past experimental data is shown in Figure 5. It shows that both experimental and numerical load-displacement curves are well-matched with each other. The Mean Absolute Percentage Error (MAPE) between two curves is calculated as 1.91% and it is in the acceptable level. Therefore, it was decided to use the developed 2D axisymmetric model for this study.

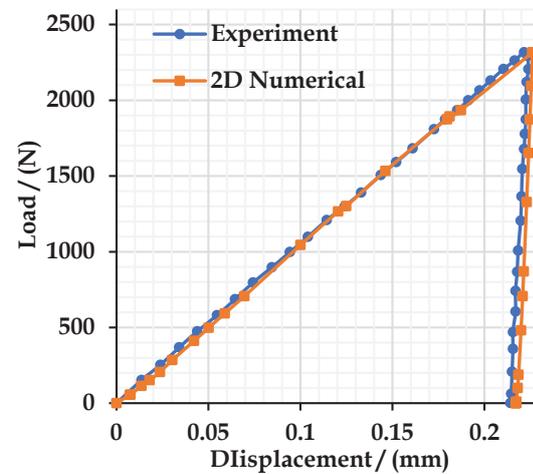

Figure 5 - Validation of Ball Indentation Model with Past Experimental Results

### 4. Sensitivity of Brinell Hardness Number (BHN) to Structural Steel Material Properties

In this section, the sensitivity of BHN to each structural steel material property ( $E$ ,  $\sigma_y$ ,  $\alpha$  and  $n$ ) is analysed. The ranges of the material properties are selected by considering the structural steel material property ranges. Table 2 gives the selected material property values for defining material combinations in this study.

Table 2 - Parameters Used for Defining the Material Combinations

Material Parameter	Selected values
$E$ (GPa)	190, 195, 200, 205, 210
$\sigma_y$ (MPa)	275, 300, 325, 350, 375, 400
$n$	0, 0.1, 0.2, 0.3, 0.4, 0.5
$\alpha$	7, 10, 15, 16, 20, 23

BHN is calculated for all the material combinations by using their numerical load-displacement curves which are obtained from the developed validated 2D axisymmetric FE models. The equation used for calculating BHN is given in Eq. (2).

$$BHN = \frac{2P}{\pi D(D - \sqrt{D^2 - d^2})} = \frac{P}{\pi Dt} \quad \dots(2)$$

where,

- $P$  = Applied load in kilograms ( $kg$ )
- $D$  = Diameter of indenter ( $mm$ )
- $d$  = Diameter of the indentation ( $mm$ )
- $t$  = Indentation depth ( $mm$ )

Usually, no measuring unit is used for BHN. In calculating BHN, the standard applied load for 5 mm diameter indenter is 750 kg [32].

The sensitivity of BHN concerning each structural steel material property is calculated using the sensitivity definition provided in mathematics. Mathematically, sensitivity is quantitatively defined as follows [33].

$$\text{Sensitivity of } y \text{ with respect to } x = \frac{\% \text{ change in } y (dy/y)}{\% \text{ change in } x (dx/x)} \quad \dots(3)$$

The following example describes the sensitivity definition more clearly.

Let's consider the variation of  $y$  with  $x$  given by the function  $y = f(x)$  as illustrated in Figure 6 and derivative of  $y$  is given by  $\frac{dy}{dx} = f'(x)$ . Then, the percentage change in  $y$  is given by Eq. (4) and the sensitivity of  $y$  with respect to  $x$  is given by Eq. (5) as follows.

$$\frac{dy}{y} = \frac{f'(x)}{f(x)} dx \quad \dots(4)$$

$$\frac{(dy/y)}{(dx/x)} = \frac{f'(x)}{f(x)} x \quad \dots(5)$$

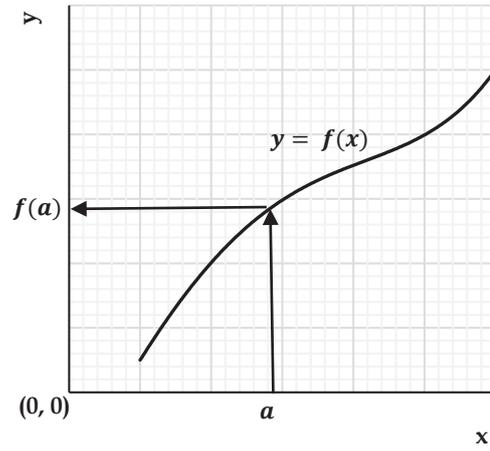

Figure 6 - Illustration of the function  $y = f(x)$

For a given point in  $x$ , the sensitivity of  $y$  with respect to  $x$  can be described as follows.

If  $x = a$ ,  $y = f(a)$  and  $\frac{dy}{dx} = f'(a)$ , then,

$$\text{Sensitivity of } y \text{ with respect to } x \text{ at } x = a = \frac{f'(a)}{f(a)} a \quad \dots(6)$$

That means, if  $x$  changes by 1 unit,  $y$  is going to change by  $\frac{f'(a)}{f(a)} a$  units at  $x = a$ . Here, the sensitivity of  $y$  can be a positive value or a negative value. If it is a positive value, that means for 1 unit change in  $x$ ,  $y$  is going to change in the same direction of  $x$  and if it is a negative value, that means for 1 unit change in  $x$ ,  $y$  is going to change in the opposite direction of  $x$ . By using the above definition, the sensitivity of BHN with respect to each structural steel material property is calculated.

#### 4.1 Sensitivity of BHN to Young's Modulus ( $E$ )

To identify the behaviour of BHN with Young's modulus ( $E$ ), steel specimens with  $\sigma_y = 350$  MPa,  $n = 0.2$  and  $\alpha = 7$  are employed with different Young's modulus values; 190 GPa, 195 GPa, 200 GPa, 205 GPa and 210 GPa. Figure 7 illustrates the load-displacement curves obtained from the validated FE model for different Young's modulus values. From Figure 7, it can be seen that the maximum value of the loading curve increases with the increasing of the Young's modulus of the structural steel material.

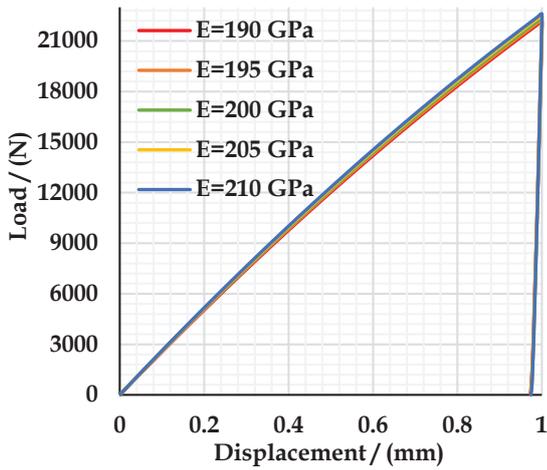

Figure 7 - Load-Displacement Curves for different Young's Modulus Values (for  $\sigma_y = 350 \text{ MPa}$ ,  $n = 0.2$  and  $\alpha = 7$ )

Using Eq. (2) and above load-displacement curves, BHN is calculated for structural steel materials with different Young's modulus values. The variation of BHN with the Young's modulus is shown in Figure 8. From the variation, it can be said that there is a good power relationship between the Young's modulus of structural steel material and the BHN.

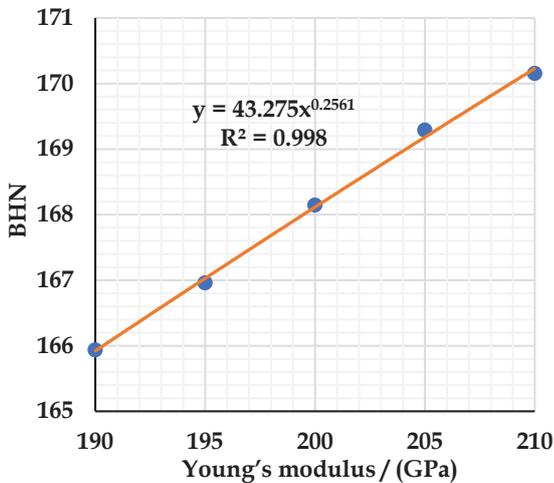

Figure 8 - Variation of BHN with the Young's Modulus

Considering Eq. (3), the sensitivity of BHN to the Young's modulus is calculated as 0.2561. That means if the Young's modulus increases by 1 unit, BHN is going to increase by 0.2561 units for all Young's modulus values. Hence, it can be said that the sensitivity of BHN to the Young's modulus is a constant for all structural steel materials. See Figure 9 for the variation of the sensitivity of BHN to the Young's modulus.

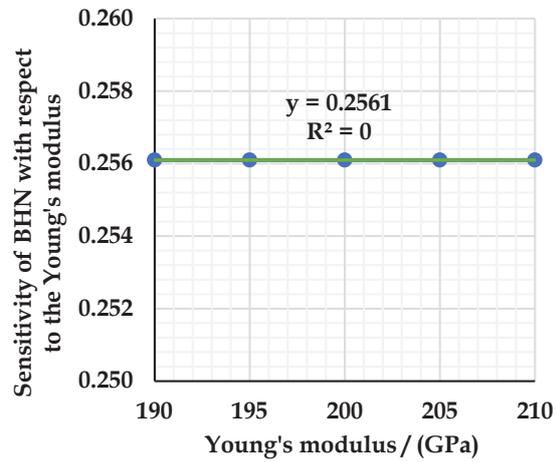

Figure 9 - Variation of Sensitivity of BHN to the Young's Modulus

#### 4.2 Sensitivity of BHN to the Yield Strength ( $\sigma_y$ )

Steel specimens with  $E = 210 \text{ GPa}$ ,  $n = 0.2$  and  $\alpha = 7$  are employed with the different yield strength ( $\sigma_y$ ) values, 275 MPa, 300 MPa, 325 MPa, 350 MPa, 375 MPa and 400 MPa to identify the behaviour of BHN with the yield strength of the structural steel material. The load-displacement curves obtained from the validated FE model for different yield strength values are shown in Figure 10. From the variation of load-displacement curves, it can be said that the maximum value of the loading curve increases with the increasing of the yield strength of the material.

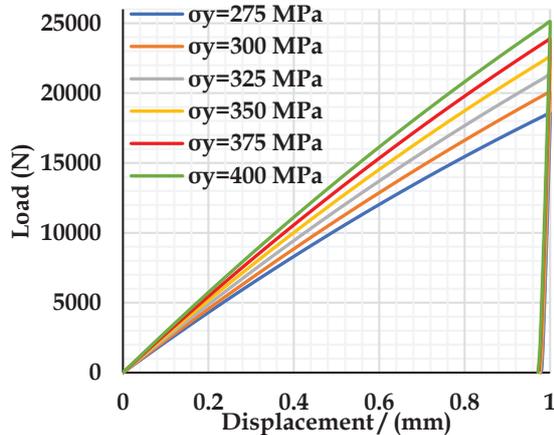

Figure 10 - Load-Displacement Curves for different Yield Strength Values (for  $E = 210 \text{ GPa}$ ,  $n = 0.2$  and  $\alpha = 7$ )

By using the above load-displacement curves and Eq. (2), BHNs are calculated for structural steel materials with different yield strength values. The variation of BHN with the yield strength is shown in Figure 11. It shows that there is a good linear relationship between the yield strength of the steel material and the BHN.

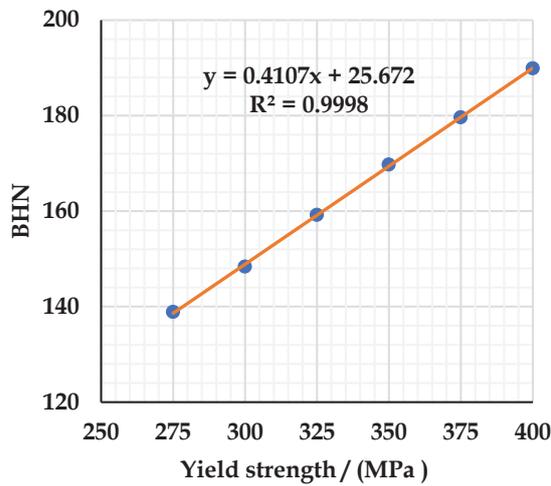

Figure 11 - Variation of BHN with the Yield Strength

According to Eq. (3), the sensitivity of BHN to the yield strength is obtained as  $\frac{0.4107\sigma_y}{0.4107\sigma_y+25.672}$ .

That means if the yield strength increases by 1 unit at  $\sigma_y = \sigma_{y0}$ , BHN is going to increase by  $\frac{0.4107\sigma_{y0}}{0.4107\sigma_{y0}+25.672}$  units. See Figure 12 for the variation of the sensitivity of BHN to the yield strength for different yield strength values. It can be seen that the sensitivity of BHN to the yield strength increases with the increasing of the yield strength of the material.

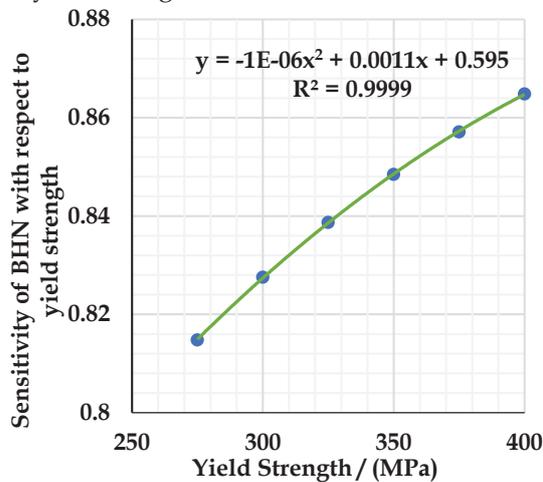

Figure 12 - Variation of Sensitivity of BHN to the Yield Strength

#### 4.3 Sensitivity of BHN to the Ratio ( $\alpha$ ) between the Strain at Beginning-Point of Strain Hardening ( $\epsilon_{st}$ ) and the Yield strain ( $\epsilon_y$ )

To identify the behaviour of BHN with the  $\alpha$  value, steel specimens with  $E = 210 \text{ GPa}$ ,  $\sigma_y = 350 \text{ MPa}$  and  $n = 0.2$  are employed with different  $\alpha$  values, 7, 10, 15, 16, 20 and 23. Figure 13 shows the load-displacement curves obtained from the validated FE model for different  $\alpha$  values.

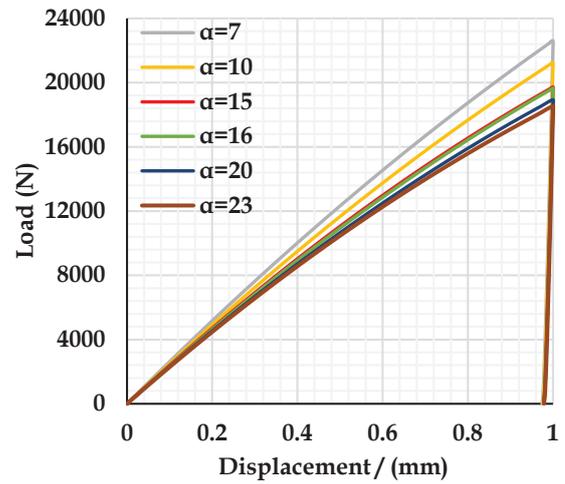

Figure 13 - Load-displacement Curves for different  $\alpha$  Values (for  $E = 210 \text{ GPa}$ ,  $\sigma_y = 350 \text{ MPa}$  and  $n = 0.2$ )

By considering the variation of load-displacement curves, it can be said that the maximum value of the loading curve decreases with the increasing of the  $\alpha$  value of the steel material.

Then BHNs are calculated for structural steel materials with different  $\alpha$  values using Eq. (2). The relevant data obtained from the numerical load-displacement curves is shown in Figure 13. The variation of BHN with the  $\alpha$  value is shown in Figure 14. It shows that there is a good power relationship between the  $\alpha$  value of the steel material and the BHN.

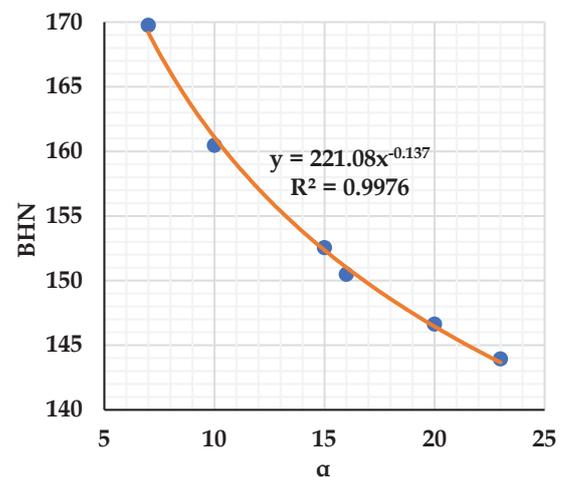

Figure 14 - Variation of BHN with the  $\alpha$  Value

Eq. (3) is used to calculate the sensitivity of BHN to the  $\alpha$  value and it is obtained as -0.137. That means if the  $\alpha$  value increases by 1 unit, BHN is going to decrease by 0.137 units for all  $\alpha$  values. Therefore, it can be said that the sensitivity of BHN to the  $\alpha$  value is a constant for all structural steel materials. The variation

of the sensitivity of BHN to the  $\alpha$  value for different  $\alpha$  values is shown in Figure 15.

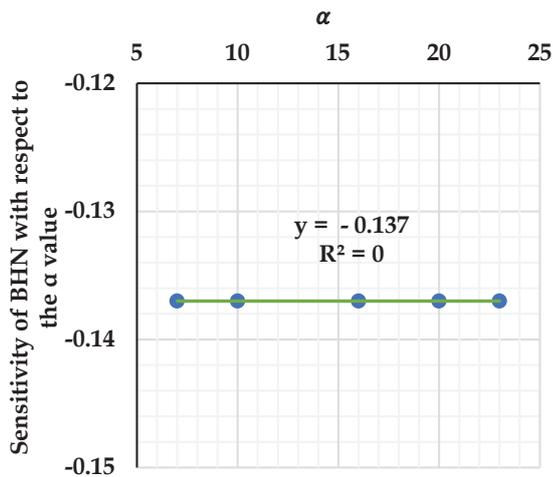

Figure 15 - Variation of Sensitivity of BHN to the  $\alpha$  Value

#### 4.4 Sensitivity of BHN to the Strain Hardening Exponent ( $n$ )

Steel specimens with  $E = 210 \text{ GPa}$ ,  $\sigma_y = 350 \text{ MPa}$  and  $\alpha = 7$  are employed with different strain hardening exponent ( $n$ ) values, 0, 0.1, 0.2, 0.3, 0.4 and 0.5 to identify the behaviour of BHN with the strain hardening exponent. Figure 16 shows the load-displacement curves obtained from the validated FE model for different strain hardening exponent values.

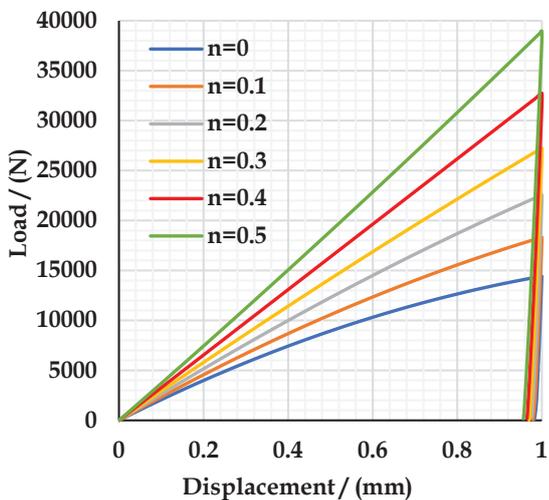

Figure 16 - Load-displacement Curves for different Strain Hardening Exponents (for  $E = 210 \text{ GPa}$ ,  $\sigma_y = 350 \text{ MPa}$  and  $\alpha = 7$ )

Considering the variation of load-displacement curves, it can be said that the maximum value of the loading curve increases with the increasing of the strain hardening exponent of the structural steel material.

To identify the variation of BHN with the strain hardening exponent, BHNs are calculated for structural steel materials with different strain

hardening exponent values. For that, Eq. (2) and Figure 16 load-displacement curves are employed. Then, the variation is plotted and it shows that there is a good polynomial relationship between the strain hardening exponents of the steel material and the BHN as shown in Figure 17.

The sensitivity of BHN to the strain hardening exponent is obtained as  $\frac{193.954n^2+203.62n}{96.977n^2+203.62n+123.98}$  considering Eq. (3). That means if strain hardening exponent increases by 1 unit at  $n = n_0$ , BHN is going to increase by  $\frac{193.954n_0^2+203.62n_0}{96.977n_0^2+203.62n_0+123.98}$  units. Figure 18 shows the variation of the sensitivity of BHN to the strain hardening exponent for different strain hardening exponent values. It shows that the sensitivity of BHN to the strain hardening exponent increases with the increasing of the strain hardening exponent of the steel material.

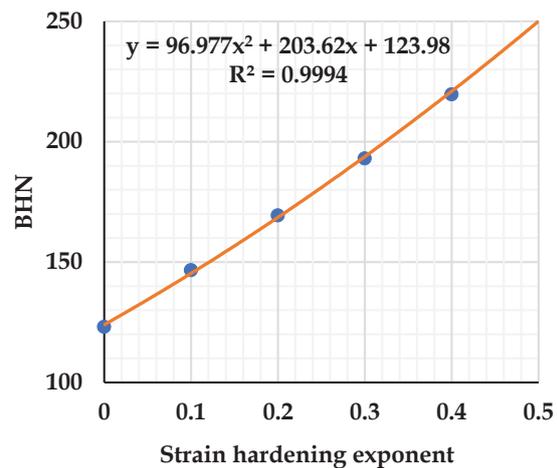

Figure 17 - Variation of BHN with the Strain Hardening Exponent

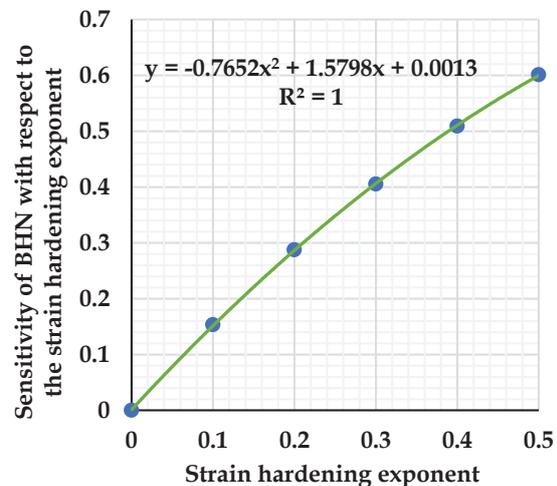

Figure 18 - Variation of Sensitivity of BHN to the Strain Hardening Exponent

#### 4.5 Comparison of the Sensitivity of BHN to Structural Steel Material Properties

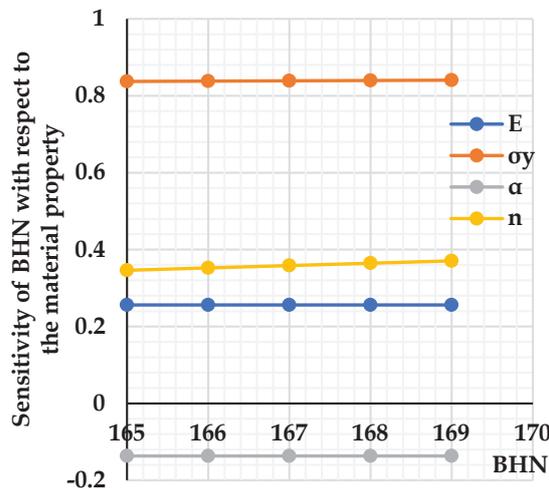

Under this section, a comparison is made for the sensitivity of BHN by considering all four structural steel material properties which are discussed above. For that, variation of BHN with each material property (Figures 8, 11, 14, 17) is considered to select a common BHN range for all four material properties.

Table 3 gives the structural steel material property ranges considered in this study and their BHN ranges calculated from the derived relationships.

**Table 3 - Structural Steel Material Property Ranges and their BHN Ranges**

Structural steel material property range	Relevant BHN range
$E$ 190 GPa to 210 GPa	165 - 171
$\sigma_y$ 275 MPa to 400 MPa	138 - 190
$\alpha$ 7 to 23	169 - 144
$n$ 0 to 0.5	123 - 169

From the table, it can be said that BHN range 165 to 169 is common for all four material properties. Hence, the comparison is made by varying the BHN from 165 to 169. Figure 19 shows the variation of the sensitivity of BHN to each material property with the BHN.

**Figure 19 - Variation of the Sensitivity of BHN for Each Structural Steel Material Property**

From Figure 19, it can be seen that BHN has the highest sensitivity to the yield strength and the lowest sensitivity to the  $\alpha$  value of the steel material. To the Young's modulus and strain hardening exponent, the sensitivity of BHN is in the middle region and they have

approximately similar sensitivity values. The sensitivity of BHN to the yield strength and strain hardening exponent is increasing with the increasing of the material property. However, the sensitivity of BHN to the Young's modulus and the  $\alpha$  value is not going to change with the material property.

By considering the sensitivity behaviours of BHN to each structural steel material property, an inverse analysis method can be developed to determine the material properties,  $E$ ,  $\sigma_y$ ,  $\alpha$  and  $n$  of an unknown steel member using the Brinell hardness test. In that case, it is better to give more attention to the  $\alpha$  value, since BHN has less sensitivity to the  $\alpha$  value of the structural steel material than other properties.

## 5. Conclusions

In this study, numerical analysis has been carried out to obtain the BHN for each combination of structural steel material properties using finite element analysis. First, a 2D axisymmetric FE model is developed to simulate the indentation hardness test and validated. Then, load-displacement curves are obtained for each combination of steel material properties and BHNs are calculated using Eq. (2). Finally, the sensitivity of BHN to each material property is calculated considering the definition given in Eq. (3) and their comparison is made.

The following are the main conclusions of this study:

- The maximum value of the load-displacement curve and the BHN of structural steel material are increasing with the increasing of the Young's modulus, yield strength and the strain hardening exponent and it is decreasing with the increasing of the  $\alpha$  value of the material.
- BHN has good power relationships with the Young's modulus and the  $\alpha$  value, a good linear relationship with the yield strength and a good polynomial relationship with the strain hardening exponent of the structural steel material.
- BHN has a smaller sensitivity to the  $\alpha$  value and it has the highest sensitivity to the yield strength of the structural steel material.

- The sensitivity of BHN to the Young's modulus and the  $\alpha$  value of the structural steel material are constants. That means, if the Young's modulus or the  $\alpha$  value of the steel material changes by 1 unit, BHN is going to change by a constant value of units.
- The sensitivity of BHN to the yield strength and the strain hardening exponent of the structural steel material is varying with the material property value.

From this sensitivity analysis, the effect of structural steel material properties,  $E$ ,  $\sigma_y$ ,  $\alpha$  and  $n$  to the BHN can be identified. Therefore, our next step is to develop an inverse analysis method based on hardness test to determine material properties of an unknown steel material which has a plastic plateau in its true stress-strain behaviour. For that, we are planning to use the sensitivity analysis results of this study.
